

ISL6271A

Integrated XScale Regulator

FN9171
Rev 2.00
August 10, 2015

The ISL6271A is a versatile power management IC (PMIC) designed for the Xscale type of processors. The device integrates three regulators, two fault indicators and an I²C bus for communication with a host microprocessor. Two of the three regulators function as low power, low drop out regulators, designed to power SRAM and phase-lock loop circuitry internal to the Xscale processor. The third regulator uses a proprietary switch-mode topology to power the processor core and facilitate Dynamic Voltage Management (DVM), as defined by Intel.

Since power dissipation inside a microprocessor is proportional to the square of the core voltage, Intel XScale processors implement DVM as a means to more efficiently utilize battery capacity. To support this power saving architecture, the ISL6271A integrates an I²C bus for communication with the host processor. The processor, acting as the bus master, transmits a “voltage level” and “voltage slew rate” to the ISL6271A appropriate to the processing requirements; higher core voltages support higher operating frequencies and code execution. The bus is fully compliant with the Phillips® I²C protocol and supports both standard and fast data transmission modes. Alternatively, the output of the core regulator can be programmed in 50mV increments from 0.85V to 1.6V using the input Voltage ID (VID) pins. All three regulators share a common enable pin and are protected against overcurrent, over temperature and undervoltage conditions. When disabled via the enable pin, the ISL6271A enters a low power state that can be used to conserve battery life while maintaining the last programmed VID code and slew rate. An integrated soft-start circuit transitions the ISL6271A output voltages to their default values at a rate determined by an external soft-start capacitor.

Pinout

Features

- Three Voltage Regulators (1 Buck, 2 LDOs)
- High-Efficiency, fully-Integrated synchronous buck regulator with DVM
- 800mA DC output current for the buck regulator
- Proprietary ‘Synthetic Ripple’ Control Topology
- Greater than 1MHz Switching Frequency
- Diode emulation for light load efficiency
- I²C Interface Module for DVM from 0.85V to 1.6V
- Optional fixed 4-bit VID-control in lieu of DVM
- Small Output Inductor and Capacitor
- Battery Fault signal
- Input Supply Voltage Range: 2.76V-5.5V
- 4x4 mm QFN Package:
 - Compliant to JEDEC PUB95 MO-220 QFN - Quad Flat No Leads - Package Outline
 - Near Chip Scale Package footprint, which improves PCB efficiency and has a thinner profile
- Pb-free Available (RoHS Compliant)

Applications

- PDA
- Cell Phone
- Tablet Devices
- Embedded Processors

Functional Pin Description

PVCC - Input power to the core switching regulator. This voltage is typically supplied by a the primary, single-cell Li-ion battery or power adapter.

VCC. Voltage source for control circuitry. Must be held within 0.3V of PVCC.

BBAT. Secondary back-up voltage used to provide an indication of the main battery status when the main battery is low or absent. BBAT is typically a coin cell device and must be maintained between 1.5V and 3.75V if it is not connected to VCC pin. Connect it to VCC if BFLT# function is not used.

PHASE. The output switching node that connects to the output inductor to generate the processor core voltage.

VOUT. Output voltage of the core regulator. Programmable from 0.85 to 1.6V via the integrated I²C bus or VID pins.

LVCC. Input voltage to the VSRAM and VPLL LDO pass elements. To minimize power loss across the pass element this should be tied to a pre-regulated system voltage between 1.8V and 2.5V. LVCC can operate from the main battery input when lower voltages are unavailable.

VPLL. 1.3V LDO regulator designed to supply power to the phase-locked loop circuitry internal to the microprocessor.

VSRAM. 1.1V LDO regulator designed to supply power to the microprocessor SRAM circuitry.

FB. Core voltage feedback (to the error amplifier) via an external compensation resistor.

SOFT. An external capacitor connected between this pin and ground controls the regulators output rise time. The start-up ramp begins when VCC reaches its power-on-reset (POR) rising threshold and the EN pin is high.

EN - The ISL6271A outputs are enabled when a voltage greater than 2V is applied to the EN pin. The core regulator output MOSFETs bridge is turned off and the LDOs are disabled when EN is pulled low.

BFLT# - Battery fault indicator. A high level indicates the adequacy of the battery for regulator start-up. Designed to interface with the processor General Purpose IO, this pin is actively pulled low when the main battery is absent.

PGOOD - An open-drain output that indicates the status of the three regulators. It is pulled low when any of the regulators are outside their voltage tolerances.

VIDEN - Pull this pin low to enable I²C communication. Connecting this pin to VCC disables the I²C bus and enables the VID inputs. In this mode the slew rate is fixed at a value determined by the soft-start capacitor.

SCL (VID0) - This is a dual function pin. When VIDEN is low it acts as the I²C clock input (SCL). When VIDEN is high this pin acts as bit 0 to the VID DAC.

SDA (VID1) - This is a dual function pin. When VIDEN is low it acts as the I²C data/address line (SDA) used to transfer voltage level and slew rate instructions to the ISL6271A. When VIDEN is high this pin acts as bit 1 to the VID DAC.

VID2, VID3 - VID inputs to the error amplifier reference DAC. Used to control the core voltage when VIDEN is high.

GND - Device signal ground. Connected to PGND at a single point to avoid ground loops.

PGND - Power ground return connection for the internal synchronous rectifier.

Operational Description

Initialization

Upon application of input power to the ISL6271A, the power good signal (PGOOD) will switch from low to high after four conditions are met - (1) VCC exceeds the power on reset “rising threshold”, (2) the EN pin is high and (3) the LDO input voltage (LVCC) is greater than 1.6V, (4) All three outputs are in regulation. Figure 16 illustrates this start-up sequence. The outputs are powered on under a soft-start regime with the core output voltage defaulting to 1.3V (unless under VID control) and the LDOs at their fixed output levels. Once the outputs are in regulation, the ISL6271A will respond to a voltage change command via the I²C bus.

When under VID control (VIDEN = HI), the Vout will rise to a value set by VID pins. The slew rate is always fixed by the soft-start capacitor.

Core Regulator Output

The ISL6271A core regulator is a synchronous buck regulator that employs an Intersil proprietary switch-mode topology known as Synthetic Ripple Regulation (SRR). The SRR architecture is a derivative of the conventional hysteretic-mode regulator without the inherent noise sensitivities and dependence on output capacitance ESR. The topology achieves excellent transient response and high efficiency over the entire operating load range. Output voltage ripple is typically under 5mV in Continuous Conduction Mode (CCM) and under 10mV in DCM (diode emulation). The output core voltage is derived from the main battery pack (typically a single cell Li-ion battery) and is programmable in 50mV steps between 0.85 and 1.6V. The output regulator set-point is controlled by an on-chip DAC which receives its input either from the I²C bus or the VID input pins (VID0-VID3). Table 1 identifies the VID code states and corresponding output voltage. To minimize core voltage over-shoot and under-shoot between code states, the ISL6271A implements programmable, voltage slew rate control via the I²C bus. The slew rate is a function of the data in the slew rate control register and also the soft-start capacitor; the slew rates in Table 2 assume a soft-start capacitor value of 10nF. Once the regulator has initialized, the IC can be placed in a low quiescent state by pulling low the EN pin. The regulator ‘remembers’ the last programmed voltage level and slew rate after each subsequent EN cycle, and return to the previous set-point once EN is brought high.

Soft-Start and Slew Rate Control

To assure stability and minimize overshoot at start-up and during DVM transitions, the ISL6271A implements a controlled rise time of each regulator output. The Slew Rate control bits in Table 2 are used to route one of 4 current sources to the SOFT pin. These current sources along with the soft-start capacitor will control the rate of rise of voltage during DVM transitions. The recommended 10nF soft-start capacitor will result in a typical slew rate of 1mV/μs at start-up and the programmable DVM slew rates defined in Table 2. Slower or faster start-up and DVM transactions can be accommodated by selecting a smaller or larger soft-start capacitor. By default bits D5 and D4 are set to “01” corresponding to a SS current of 10μA. Writing “00” will result in a 5μA of current whereas “10” corresponds to 24μA and “11” corresponds to a typical source current of 47μA. The expression $i = cdv/dt$ can be used to solve for the appropriate slew rate.

Example: Desired slew rate = 10mV/μs fixed slew rate and the slew rate control bits are set to “11”. Then:

$I_{source} = I_{11} = 47\mu A$ (nominal), therefore

$$C = \frac{I_{source}}{\frac{dv}{dt}} = \frac{47\mu A}{\frac{10mV}{\mu s}} = 4.7nF \quad (EQ. 1)$$

NOTE: Intel specifies a maximum slew rate for Vcore transitions. To satisfy this requirement, the SS capacitor and SOFT pin sink/source current tolerances must be considered. Refer to the Electrical Specification table and appropriate Intel documents for details. Note that when D5 and D4 are set to “11” the maximum source current is 64μA. Under this condition, the slew rate would be 16mV/μs if a 4.7nF SS capacitor varied by 15% negative. For this reason a 6.8nF capacitor is recommended when D5 and D4 are set to “11”.

Undervoltage and Overvoltage on Vout

If the output voltage of the switching regulator exceeds 114% of the SOFT pin voltage (programmed DAC voltage) for longer than 1.5μs, an overvoltage fault will be tripped and the phase node will be three-stated. Hysteresis requires the voltage to fall to 106% before the fault is automatically reset.

An undervoltage occurs when the output voltage falls below 86% of SOFT pin voltage. Once this fault is triggered, hysteresis sets the reset point to 94%. An undervoltage condition will occur if the output DC current plus the ripple exceeds the current limit point for a period longer than the output capacitance hold-up time.

Loop Compensation

All three regulators are internally compensated for stability; however, an external resistor connected between the core regulator output and the FB pin can be used to alter the closed loop gain of the switching regulator and optimize transient response for a given output filter selection. The following combinations of component values are recommended:

TABLE 3. RECOMMENDED KEY COMPONENT VALUES FOR CORE REGULATOR

LO	COU _T	RCOMP
3.3μH	4.7μF	100kΩ
4.7μH	10μF	50kΩ

Overcurrent Limit

To protect against an overcurrent condition, the core regulator employs a proprietary current sensing circuit that monitors the voltage drop across the internal upper MOSFET. When an overcurrent condition is detected the controller will limit the output current and if the condition persists, the output voltage level will drop below the undervoltage level tripping the PGOOD indicator. See “Applications section” for details.

SRAM and PLL LDOs

The two linear regulators on the ISL6271A are designed to satisfy the power requirements of the SRAM and phase-lock loop circuitry internal to XScale processors. These regulators share a common input voltage pin (LVCC) that can be tied to the main battery PVCC or preferably to a lower system voltage to effect a higher conversion efficiency. It is recommended that LVCC be connected to pre-regulated voltages between 1.8V - 2.5V.

Each LDO is internally compensated and designed to operate with a low-ESR ceramic capacitor (X5R or better) between 2.2μF and 3.3μF. Both LDOs have overcurrent, undervoltage and thermal protection and share a common enable signal (EN) with the core regulator, allowing them to be enabled/disabled together as required by the processor.

BFLT#

The logic state of the BFLT# output indicates whether the main battery input is adequate to power the system in normal operation. A battery low (or absent) condition is indicated by this pin being pulled low. Upon initial application of battery power, it will indicate a battery good condition when the battery voltage is greater than 2.8V (nominal), and it will sustain the battery good indication until the voltage drops below 2.6V (nominal). The output is pulled actively low, with no main battery connected by tapping power from the secondary input, BBAT. It is actively driven to BBAT when the main battery is within the POR thresholds.

BBAT

The BBAT pin is an input voltage to the ISL6271A that supports the BFLT# indicator function as described above. When the

main battery is absent, or of inadequate potential, the BBAT input voltage supplies power to support the BFLT# indicator. The input voltage must be between 1.5V and 3.75V for proper operation and is typically supplied from the system back-up battery. The maximum current drain from the BBAT pin is 0.1µA.

PGOOD

PGOOD is an open-drain output that indicates the status of the three regulators (VOUT, VSRAM, VPLL). This output is held low until all outputs are within their specified voltage tolerance. As soon as outputs are in regulation, the output is released and pulled high by an external resistor tied to a compliant system voltage. This output can be AND'd with other system power-good indicators that also have open-drain outputs. Note that this is not a latched output and under a soft short condition on any of the regulators it is possible to see this pin oscillate at a frequency proportional to the fault current level and the fault monitoring hysteresis internal to the ISL6271A regulator.

PHASE Node Ring Damping Circuit

To enhance system reliability and minimize radiated emission, the ISL6271A implements a PHASE node snubber while operating in diode emulation. The active snubber places a 50Ω (nominal) resistor across the output inductor when the low side synchronous rectifier is turned off to prevent reverse current.

Inter-IC Communications

Communication between the host processor and the ISL6271A takes place over a two-wire I²C interface. The bus consists of one bidirectional signal line, SDA (data), and a clock pin input, SCL, generated by the bus master. Both pins are pulled-high to a system voltage with external pull-up resistors. A typical pull-up resistor value for a single master/slave interface operating in normal mode is 5kΩ.

See the Phillips specification listed in the reference section for specific details on the selection of the pull-up resistor. The bus

supports both standard mode and fast mode data rates as defined by the Phillips protocol. A typical I²C transmission is illustrated in Figure 17. When the bus-resident master (processor) wants to communicate with a bus-resident slave (ISL6271A), it will pull the SDA line low while the SCL line is still high. This signals a “start” condition. It will then clock the address of the desired slave device at a rate of one bit per clock cycle. The address is embedded in the first seven bits of the first byte transfer, with the eighth bit giving the directional information (Read/Write) for the next byte of information. When the slave detects an address match, it will hold the SDA line low during the ninth clock pulse to acknowledge a match (ACK). If the direction bit indicates a “write” (send) byte, the slave will receive the byte clocked in by the master and will give an “acknowledge” by again pulling the SDA line low during the ninth clock cycle. The master then can either terminate transmission by issuing a “stop” bit, or continue to transfer successive bytes until complete.

Multiple successive bytes can be transferred with only an acknowledge bit separating them until a “stop” or repeated “start” signal is given by the master. The data embedded in the byte is latched into its appropriate register(s) on the rising edge of the SCL during the acknowledge pulse and is applied to the ISL6271A DAC. The internal DAC on the ISL6271A converts the 4 bit digital input as defined in Table 1 into the reference voltage of the core regulator error amplifier.

If the master issues a ‘read’ command to the ISL6271A, to verify the contents of the internal registers, the device will place the byte on the bus to be clocked in by the master. After the host master receives the byte, the cycle is terminated by a “NOT acknowledge” signal, and a ‘stop’ bit. A ‘stop’ is generated by releasing the SDA line to pull high during a high state on the SCL line.

FIGURE 18. INTERFACE BIT DEFINITION AND PROTOCOL

VID and Slew Rate Program Register

In a typical XScale configuration, the processor’s “Power Manager” will issue the voltage and slew rate commands to the ISL6271A over its PWR_I²C bus after the ISL6271A acknowledges its address. The data byte is composed of two pieces of ‘set’ information: The prescribed voltage level embedded in bits D0-D3, and the prescribed transition slew rate (from the previous voltage to the target voltage) embedded in bits D4-D5. Each set of bits is transmitted MSB first. This protocol is depicted in Figure 18.

Application Guidelines

Every effort should be made to place the ISL6271A as close as possible to the processor, with the orientation favoring the shortest voltage routing. The regulator input capacitors should be located close to their respective input pins.

All output capacitors should be kept close to their respective output pins with the ground pins connected immediately to the ground plane. Care should be taken to avoid routing sensitive, high impedance signals near the PHASE pin on the controller, and the attendant PCB traces.

To minimize switching noise, it is important to keep the loop area associated with the phase node and output filter as short as possible. It is also important that the input voltage decoupling capacitor C7 be located as close to the PVCC pin as possible and that it has a low impedance return path to the PGND pin. In general a good approach to layout is to consider how switching current flows in a circuit, and to minimize the loop area associated with this current. In the case of the switching regulator, current flows from C7 through the internal upper P-MOSFET, to the load through the output filter and back to the PGND pin. *To maximize the effectiveness of any decoupling capacitor, minimize the parasitic inductance between the capacitor and the circuit it is decoupling.* Notice that Figure 19 illustrates the SIGNAL ground with RED highlighting. All components associated with these terminals should be tied together first. Be sure to make only one connection between this net and the PGND pin to avoid ground loops and noise injection points into sensitive analog circuitry.

FIGURE 19. TYPICAL APPLICATION CIRCUIT

Loop stability calculations are simplified when using the ISL6271A and are limited to the selection of a single feedback resistor, R_{comp} . The R_{comp} resistor will affect the closed loop gain of the internal compensation network as in Equation 2. Empirical and theoretical testing suggests that a value of 50K will provide the most ideal transient response to the expected XScale load and voltage transitions when used with the recommended 4.7 μ H output inductor and 10 μ F output capacitor. Using the ISL6271A evaluation board, a 50K feedback resistor resulted in a minimum of 60 degrees of phase margin under worst case line and load transitions. When placing the R_{comp} feedback resistor, be sure to avoid routing it parallel to switching circuits, especially the phase node, that could otherwise induce noise into the FB pin.

$$G_{comp} = \frac{(R_c \cdot C_c \cdot s + 1)}{R_{comp} \cdot C_c \cdot s} \quad (\text{EQ. 2})$$

Overcurrent Protection and Ripple Current

The OCL trip level inside the ISL6271A is a function of the upper PMOS output transistor's on-resistance and over-current comparator threshold voltage. The device was designed to accommodate a maximum RMS current of 800mA, and to accommodate this DC current level plus the associated ripple current, the OC limit of the ISL6271A will not trip below 950mA. Ripple current inside the ISL6271A is defined by the expression,

$$I_{ripple} = \frac{(V_{in} - V_{out})}{L \cdot f_s} \cdot \frac{V_{out}}{V_{in}} \quad (\text{EQ. 3})$$

where " f_s " is the switching frequency of the converter. The architecture of the ISL6271A is such that the switching frequency will increase with higher input voltage. This behavior attempts to keep the ripple current constant for a given output inductor, input voltage and output voltage. To minimize ripple current and preserve transient response, Intersil recommends an output inductor between 3.3 μ H and 4.7 μ H. Higher values of inductance will minimize the risk of tripping the over-current minimum threshold of 950mA.

SSR Theoretical Operation

The ISL6271A is a PWM controller that uses a novel architecture developed by Intersil called *Synthetic Ripple Regulation*. The architecture operates similar to a hysteretic converter without the deficiencies of noise sensitivities. Reduced to its simplest form, the Synthetic Ripple Regulator inside the ISL6271A is made up of three elements as illustrated in Figure 20: A transconductance amplifier (Rippler Amplifier), a window comparator with hysteresis and an Error Amplifier. While operating in continuous conduction mode, the converter has a natural switching frequency of 1.2MHz delivering an ultra low output voltage ripple and exceptional transient response as illustrated in Figures 23 and 24.

FIGURE 20. SIMPLIFIED SRR DIAGRAM

Figure 20 illustrates the two control loops inherent to the SRR architecture. The inner loop consists of the ripple amplifier, the window comparator, gate drive circuitry and the power stage. The outer loop controls the inner loop and is made up a high bandwidth error amplifier with internal and external compensation.

CCM Operation - Heavy Current

Figure 21 illustrates the SSR in CCM. When the upper P-MOSFET is turned on, the phase voltage equals the input voltage and the ripple transconductance amplifier outputs a current proportional to the difference of the input and output voltage. This current will ramp the voltage on the ripple capacitor C_r in Figure 20. As this voltage reaches the upper threshold of the hysteretic comparator, the comparator output will switch low. After a propagation delay, the upper P-MOSFET is turned off and the lower N-MOSFET is turned on, forcing synchronous rectification. At this point, the ripple amplifier now has inputs of 0V and V_{OUT} and will sink current to discharge the ripple capacitor. When the voltage across the ripple capacitor reaches the lower threshold of the hysteresis window, the window comparator outputs a high signal. After a propagation delay, the upper P-MOSFET turns on repeating the previous switching cycle.

FIGURE 21. SYNTHETIC RIPPLE REGULATION IN CCM

Light Load Operation - DCM

A light load is defined when the output inductor ripple current reaches zero before the next switching cycle. Under this condition, the ISL6271A synchronous rectifier will turn off emulating a diode to prevent negative inductor current. As explained below, the switching frequency and losses associated with turning on the synchronous rectifier will be reduced to enhance the low current efficiency. The top waveform in Figure 22 shows the phase voltage in DCM. The middle waveforms include the error amplifier voltage, ripple capacitor voltage and the boundaries of the hysteresis comparator which track the EA output. The waveform at the bottom is representative of the inductor current. Notice that in a switching cycle the inductor current rises as the upper P-MOSFET turns on, falls when the lower N-MOSFET turns on, and stays at zero after the current reaches zero as a result of diode emulation.

FIGURE 22. SRR IN DCM

To understand the ISL6271A light load operation, look carefully at the waveforms in the middle of Figure 22. Notice that the voltage across the ripple capacitor, VRP, has a minimum clamp voltage (typically 0.4V), and that the Error Amplifier can go below this voltage (typically clamped to 0.2V). In DCM, the voltage across ripple capacitor will be discharged each cycle to the clamp voltage. While the lower hysteresis is below this voltage, the ripple capacitor will remain clamped keeping the upper P-MOSFET off. As the EA voltage increases so too will the lower threshold of the hysteresis window until it reaches the ripple capacitor clamp voltage (VCLMP). At this point, the upper FET will be enabled and will turn on. The lighter the load, the lower the error amplifier output is, and the longer the ripple capacitor voltage stays at the VCLMP voltage. This results in a phase node switching frequency that is proportional to load current (that is, lower switching losses and higher efficiency at lighter loads). In DCM the switching frequency will be lower than in a heavy load, CCM.

A load transition from full load to no load will result in a finite period of time during which the error amplifier settles to a new steady state condition. As illustrated in Figure 23, the SSR architecture inherent to the ISL6271A responds within 6 μ s of the mode change, slewing the error amplifier output below the clamped ripple capacitor voltage and preventing the upper FET from turning on. Prior to reaching the new stability point, the phase node applies four phase pulses before the controller forces the output voltage to the prescribed regulation point. Once the output falls below the reference voltage the controller then pumps up the output voltage and enters its steady state DCM. Mode changes that take the converter from CCM into DCM will have much higher output voltage spike than a load step that remains in CCM. Compared with competitive solutions the ISL6271A responds very well during this severe mode change and it is more than sufficient to meet Vcore tolerance specifications as required by Intel.

FIGURE 23. CCM TO DCM MODE

Transition Between Light load and Heavy Load

Unlike most control topologies that require two sets of circuits to control the light and heavy load operation, the SRR control naturally switches between heavy and light load with the same control circuit. As the load gets lighter, the feedback forces the error amplifier output to a lower voltage and when the lower threshold of the hysteresis window is lower than VCLMP, light load operation begins. The scope shot in Figure 24 illustrates a mode transition from a DCM (10mA load current) to CCM (170mA) with trace 4 (GRN) being the command pulse that initiates the mode change. Prior to the load step, and while the converter is in DCM, the ripple voltage is approximately 10mV and the ripple frequency is 125kHz. In CCM, the converter operates at a frequency of approximately 10X that of DCM and the ripple is reduced by more than a factor of two.

Measured Core Voltage Conversion Efficiency

The actual efficiency of the ISL6271A switching regulator is illustrated in Figure 3 from 10mA to 800mA. The curves were taken at room temperature using the ISL6271A evaluation board. The output inductor used is an ultralow profile, drumcore device with a DCR of 100mΩ.

FIGURE 24. DCM TO CCM MODE TRANSITION

Thermal Management

Although the ISL6271A is characteristically a low heat generator, it will generate some heat as a result of the inefficiencies in power conversion. The worst-case internal power dissipation should be less than 250mW, translating into a 11°C rise in junction temperature above ambient. If the temperature of the chip does exceed 150° ±10°C as a result of a high ambient temperature, the controller will disable the outputs until the temperature decreases by 45°C.

Powering Intel XScale Processors

Intel identifies ten power domains required for powering XScale processors. Of these ten power domains or voltages, many may be strapped together as in Figure 25 and supplied by a single regulator. These voltages however must be applied systematically to the processor and two pins, SYS_EN and PWR_EN facilitate this power sequence. The PWR_EN pin is dedicated to enabling the CORE, PLL and SRAM power domains and should be connected to the ISL6271A enable pin. The SYS_EN pin is responsible for enabling the system regulator. Figure 25 illustrates one possible configuration using the Intersil EL7536 to power five of the 10 domains.

NOTE: Intel warns that an improper power sequence can damage the processor. Refer to the appropriate Intel applications material to ensure proper voltage sequencing.

Design Notes

Refer to Table 3, "RECOMMENDED KEY COMPONENT VALUES FOR CORE REGULATOR".

1. Do not leave pins VID2(5) or pin VID3(6) floating when using the I²C bus. Tie these pins to GND (16).
2. Make sure that load current on VOUT returns to the pin 7 (PGND). Pin 16 (GND) functions as a quiet return for the LVCC loads. Tie Pin 16 to Pin 7 at a single point as in Figure 19.
3. Select the output capacitor for VSRAM and VPLL as follows: 2.2μF < C8, C5 < 4.7μF, X5R.
4. BFLT# is internally pulled up to BBAT. Do not pullup to any other external voltage.
5. The I²C pull-up resistors will affect standby leakage power. A typical value to accommodate the I²C bus slew rate requirements in "Standard Mode" is 5K.
6. Set the soft-start capacitor to 10nF to implement a 1mV/μs slew rate of the output voltage at startup. For max slew rate, use 6.8nF soft-start capacitor.
7. Tie PGOOD to the XScale nVDD_fault pin.
8. Tie the BFLT# pin to the XScale nBatt_fault pin. The BFLT# pin is pulled up internally to BBAT. A valid BFLT# state under all conditions can be achieved by connecting BBAT to the system BACK-UP battery. Otherwise, consider the system start-up/shut-down voltage timing to determine what system voltage that BBAT can be tied to that will ensure the correct BFLT# operation. Current drain on BBAT is much less than 1μA.
9. It is a good design practice to isolate PVCC from VCC with a low pass filter (LPF) made up of a 10Ω resistor and 0.1μF ceramic capacitor. Ensure that VCC is kept within 0.3V of PVCC to avoid turning on internal protection diodes.

Internal ESD Structures

The ISL6271A input/output pins are protected from over-voltage conditions by clamping the pin to one diode drop above or below the VCC voltage rail. During shutdown it is possible that the SDA and SCL pins have a voltage greater than VCC. Under this condition, the ESD diodes will provide a reverse current path to circuitry on VCC that can act as a load on the back-up battery. To avoid this condition, interrupt VCC from external circuitry if a voltage greater than VCC is expected on any of the pins identified below.

FIGURE 26. INTERNAL ESD STRUCTURES

Layout Recommendation

FIGURE 27. COMPONENT PLACEMENT AND TOP COPPER

Since the ISL6271A can operate at a high switching frequency, it is especially important to apply good layout practices. Decoupling of the regulator’s input voltage (PVCC) and minimizing the loop area associated with the phase node output filter is essential for reliable operation. Return currents from the load should find a low impedance path to the PGND pin on the IC (Pin 8). Ideally, the core voltage would be distributed to the embedded processor on a low impedance power plane; however, a 30-50mil, short trace should be sufficient. When implementing DVM it is important to minimize inductance between the load and the output filter. The processors can command slew rates of up to 200mA/ns and local decoupling at the processor socket is essential to satisfying this requirement.

DATE	REVISION	CHANGE
August 10, 2015	FN9171.2	<ul style="list-style-type: none"> - Removed obsolete part from Ordering Information table: ISL6271ACR. - Updated Intersil logo, page 1 copyright information and disclaimer. - Added revision history and About Intersil verbiage. - Updated POD L20.4x4 to most recent revision with change as follows: Added +/- 0.05 tolerances to dimensions in Top View and Bottom View.

About Intersil

Intersil Corporation is a leading provider of innovative power management and precision analog solutions. The company's products address some of the largest markets within the industrial and infrastructure, mobile computing and high-end consumer markets.

For the most updated datasheet, application notes, related documentation and related parts, please see the respective product information page found at www.intersil.com.

You may report errors or suggestions for improving this datasheet by visiting www.intersil.com/ask.

Reliability reports are also available from our website at www.intersil.com/support
